Descriptors-Census Figures, \*Comparative Analysis, \*Economic Factors, Educational Status Comparison, \*Health Facilities, \*Medical Services, National Surveys, Personnel Needs, \*Rural Urban Differences, Statistical Surveys

A comparison of national statistics on health services available in rural and urban areas of the United States from 1935-1966 revealed a relatively lower supply of health services per capita in rural areas and significant geographic differences in the supply of trained health personnel. It was shown that medical expenditures per family tended to rise with increasing income and educational levels (both lower in rural areas); however, rurality appeared to be a specific factor in the variation in medical expenditures. Data indicated that increasing rurality was directly related to a decreasing reliance on specialists for health care. Numerous graphs and tables are presented to illustrate the discussion. (DK)

## SUMMARY

The supply of personnel in health occupations is lower on a per capita basis in rural areas than in urban areas--in 1962 there were 53.9 percent more physicians per 100,000 persons in urban areas than in rural. This may be a reflection of population sparsity or the concentration of lower incomes, both of which would contribute to the lack of support for specialized medical personnel and facilities in rural areas. Though modern transportation has lessened the need for complete local medical services and facilities, persons living in extremely rural areas still do not have the ease of access to specialized and comprehensive medical care that those living in or near metropolitan areas have. This is partly the result of a trend since about 1950 toward specialization in medical practice. In 1950, 36 percent of the physicians were in private practice compared with 61 percent in 1963. Most of these practiced in urban areas.

Family outlays for medical expenditures tend to rise as income and education increase, and are greater for families living in urban than rural areas. The use of a specializing physician is more common in a Standard Metropolitan Statistical Area (SMSA) than in a non-SMSA. Specialists were used by about 6 percent more of the urban population than the rural. Chiropractors were the exception.

The use of optometrists was uniform as measured by percentage of people with visits.

## AVAILABILITY AND USE OF HEALTH SERVICES--Rural-Urban Comparison

### INTRODUCTION

Health is an important economic variable influencing business activity and growth in rural areas. Health services are both a consumer item adding to total demand and a factor affecting productivity and the supply of goods and services available for local consumption or for export. An examination of the problems associated with rural health is important in gaining insights into the interplay of social, economic, medical, engineering, and other factors influencing the health of a population. These factors provide clues to the preliminary steps needed to shape public policy and action.

The economic data available on health services are scarce. They are not exact or uniform throughout the country. This report provides comparisons of national statistics and will give the regional planner a basis from which to work. Data presented here were compiled from various sources. To analyze a particular section or region of the country will require an in-depth and precise survey to obtain the desired results.

The method of examination in this report was to select material for comparison of rural against urban statistics, or metropolitan (about two-thirds urban) against nonmetropolitan (about three-fourths rural) data. References are made to two generally accepted definitions of rural and urban. One was established by the Bureau of the Budget which lists counties under five demographic categories from greater metropolitan to isolated rural, as follows: Counties within Standard Metropolitan Statistical Areas are classified as (1) greater metropolitan if they are in an SMSA of 1 million or more population, or (2) lesser metropolitan if the SMSA population is 50,000 to 1 million. (3) Adjacent counties are not themselves metropolitan in population, but are contiguous to metropolitan counties. All other counties are classified as isolated; (4) semirural counties contain an incorporated place (town, village, etc.) of 2,500 or more population, (5) rural counties do not.

The other definition, established by the Census Bureau, designates an urban county as one which has a population center of 2,500 or more. Any county with no population center greater than 2,500 is considered rural. The available data dictated the selection of the topics discussed.

## SUPPLY OF PERSONNEL IN VARIOUS HEALTH OCCUPATIONS

There are significant geographic differences in the supply of trained health personnel throughout the United States not only in primary professions, such as physicians and dentists, but also for other health occupations, such as nurses, pharmacists, sanitarians, sanitary engineers, and veterinarians. Table 1 summarizes the comparative data on health personnel for the five county groups in 1962. The relative densities of hospital beds and effective buying power per capita indicate that persons living in isolated, or 100 percent rural, counties are not served by as many health personnel on a per capita basis as those living in or near metropolitan areas.

The number of medical personnel is not distributed equally among the general population. Metropolitan areas attract more physicians for both economic and professional reasons. Access to and contact with medical teaching centers, major hospitals, and research institutions are important factors contributing to the concentration of physicians in metropolitan areas, as are the economic and social characteristics of the population of such areas.

Table 2 illustrates the large number of physicians who become specialists requiring higher population concentrations of urban areas to maintain their practices. In 1950, about 36 percent of physicians in private practice considered themselves specialists, 1955, 44 percent; 1960, 56 percent; and 1963, 61 percent. Between 1955 and 1963, the proportion of particular specialists in private practice (as distinguished from general practitioners) increased substantially.

<u>Private practice specialties</u>	<u>Percent</u>	
	<u>1955</u>	<u>1963</u>
Surgical . . . . .	23	32
Medical . . . . .	15	20
Psychiatry and neurology . . .	3	5
Other . . . . .	3	4

During the same period, the number of general practitioners in private practice decreased from 56 percent to 39 percent.

General practitioners were dispersed more equally among the population in 1959 and 1965 than were medical specialists who were concentrated in metropolitan areas (tables 3 and 4). The total number of G.P.s in the United States diminished substantially between 1950 and 1960, while the number of persons living in rural areas has changed little (table 5).

The absolute and relative changes from 1950 to 1960 in the total and rural population in the United States and the changes in the supply of M.D.s and G.P.s are shown in tables 5 and 6. The total population increased about 18.5 percent during this decade. The data indicate the extent to which sparsely populated areas tended to have diminished per capita medical services available in the 1950's.

The continuing decline in the number of the G.P.s is more critical for the rural population than the urban because the rural areas have relied mostly on the general practitioner and less on specialists. Also, the rural areas have fewer physicians per capita. A comparison between 1959 (fig. 1 and table 7) and 1963 statistics (fig. 2 and table 8) indicates that the availability of medical services per capita to persons living in isolated counties has shown little change, while persons living in, or near, metropolitan areas have had a considerable increase in the number of full-time specialists available (fig. 3).

Figure 4

#### INCOME AND EDUCATION EFFECTS ON ELASTICITIES

Medical expenditures per family tend to rise with increasing income and education. Much of the variation in medical expenditures is generally due to the lower levels of income and education of rural residents. However, rurality also appears to be a specific factor.

Available data relating health care expenditures to measures of income, education, and rurality allow for rough estimates of income elasticities for various educational attainments by the family head in rural and urban places.

In computing the elasticities, the available independent variables are published in relatively large class intervals. For example, educational attainment is indicated in several studies by assignment into one of three categories, namely, less than 9 years of schooling, 9-12 years, and 13+ years of schooling; income in some tabulations is assigned to one of the intervals: less than \$2,000, \$2,000-\$3,999, \$4,000-\$6,999, \$7,999-\$9,999, and \$10,000+.

In the comparison of income elasticities with respect to expenditures for physicians and for food at home, the elasticity of expenditures for food at home decreases uniformly, that of physician expenses increases (fig. 4 and table 9; see also 5). 1/

Using 1958 household survey data, Feldstein calculated an income elasticity of 0.6 for health services. The qualitative implications of medical care, i.e., the significance of elasticities of demand with respect to price and income and the elasticity of supply, are also discussed by Feldstein.

The elasticity of total medical expenses relative to income was estimated to be less than 1, as calculated in the surveys of the National Center for Health Statistics in 1962 (table 10). The same was the case for hospital, physician, dental, and medicine expenses. The elasticity was near 1 for dental expenses (highly discretionary) and only about 0.2 for hospital expenses (least discretionary). This can be observed without elaborate calculations by comparing the ranges of the respective components of expenses with the ranges of income.

Rough calculations were made of income elasticities for total hospitals, physician, and dental expenses. The midpoints of the income intervals were made to correspond to the expended amounts; the differences between midpoints were the approximations to the income differentials. To avoid the difficulties resulting from the open-end interval \$10,000+, the computations were carried out up to the family income of \$10,000.

Interpretation of table 10 takes into account expenses paid out of pocket or by the insurer but not by government or philanthropic agencies.

Calculations were made of the (partial) income elasticities of persons whose family head had less than 9 years of schooling. Again, only the income brackets under \$10,000 were considered.

The higher the education of the family head, the more erratic is the behavior of the elasticities. This may be due to sampling errors caused by the decreasing size of the population and sample, to inaccurate reporting by the households surveyed, or to actual variation among those with higher levels of education.

The fact that more free medical care was obtained by low income groups than by any other income group may have contributed somewhat to the observed discontinuities in expenses. There is very little public dental care.

Medical expenditures tend to rise as the number of years of schooling of the household head increases. Medical expenses, however, decrease as a percentage of total spending, pointing to a positive but inelastic response of medical expenses to educational attainment. In a sample of 13,728 households throughout the United States in 1960-61, the level of medical expenses per family rose from \$270 per family for those in which the head had 8 years or less of schooling to \$485 per family in which the head had more than 16 years of schooling <sup>2/</sup>. However, families with heads of higher educational attainment allocated only 6.1 percent of total spending for medical care while those with lower educational attainments allocated 7.4 percent. This seems to imply that in areas where family income and educational levels are rising, medical expenditures' share of the total gross product is falling.

Much of the inelastic response of medical expenses to education may be a spurious consequence of the correlation between education and earning ability coupled with an inelastic income response. To gain insights into effects of holding income constant, a group of farm families from the above sample was examined. Ninety-five farm families living in Appalachian counties were selected who had families of more than two persons and expenditures greater than \$2,500. With this selection, some variation due to fluctuation in income and family requirements was removed. Thirty-five families had less than an 8th grade education, with an average of 5 years. The remaining 60 averaged 10 years of schooling. The increase of 5 years in educational attainment with little change in income was related to an increase of \$52 per year in medical expenses, pointing to a positive response to educational attainment given adequate incomes.

In another group of 56 families whose expenditures were less than \$2,500 per year, the percentage of income spent on medical expenses was larger than those for the higher income families, which indicates an effort to meet medical needs with limited income. But the elasticity with respect to education was about zero for this group. Apparently, increased educational attainment would not lead to a rise in medical expenses unless additional knowledge was accompanied by higher income.

Medical expenditures per family tend to be greater inside SMSA's than outside, according to averages from a survey of 13,728 persons perviously discussed (table 11). Inside the SMSA's, medical expenditures were larger both absolutely and as a percentage of total spending among rural persons compared with urban ones. However, outside SMSA's urban families spent more per family and rural families spent less.

Income variations may explain much of the variation in spending for medical services between urban families and rural nonfarm families. There appears to be a definite influence of agriculture on spending for medical care. Persons in agriculture tend to have lower incomes but larger medical expenditures than their nonfarm neighbors (table 11).

#### USE OF HEALTH CARE SPECIALISTS

The discussion here is based on references from household interviews of the civilian, noninstitutional population. Data on specialists and general practitioners were considered to compare the populations outside of SMSA, both farm and nonfarm, with residents of SMSA's with respect to use of pediatricians, obstetricians and gynecologists, ophthalmologists, otolaryngologists, psychiatrists, dermatologists, orthopedists, chiropractors, optometrists, and podiatrists. The data provide further insights into the impact of income, education, and rurality on expenditures for medical services and suggest that some of the variations discussed previously are due to the use of specialists.

Increasing rurality is directly related to a decreasing reliance on specialists for health care (tables 12-22 and fig. 5). There was greater use of specialist physicians in SMSA's than in non-SMSA's. In the latter group, a larger percentage of nonfarm people used each specialist group than farm people. The use of optometrists, as measured by the percentage of people with visits and average number of visits per patient, was generally uniform throughout all areas (table 12 and fig. 5).

An exception to the general rule was that use of chiropractors increased with increasing rurality of the area (table 13). This fact cannot be explained on the basis of income and education. For example, the population with family income under \$4,000, where the family head had less than 9 years of school, had only 2.2 percent of its members as users of chiropractic services. The population with family income under \$2,000 per year had a corresponding frequency of 2.0 percent. The fraction of farm population outside SMSA's with chiropractic visits had 4.3 percent, while the fraction of the nonfarm population outside SMSA's had a rate of 2.7 percent (table 14).

The use of pediatricians by persons under 17 years of age shows strong residence differentials. The rate of use within SMSA's was six times that of farm non-SMSA, and twice that of nonfarm non-SMSA. However, it is difficult to determine from these sources whether income and education largely explain these differences. For example, the fraction of U.S. population under 17 years of age in families with income under \$4,000 and whose head had less than 9 years of education, was 4 percent. The percentage was the same for the farm non-SMSA population under 17 (table 15 and fig. 6).

# PERCENTAGE OF POPULATION WHO CONSULTED SPECIALISTS

By Income and Education of Head of Family

Figure 5

Figure 6

The use of obstetricians and gynecologists shows some numerical relations to the use of pediatricians. The farm population with visits outside of SMSA's was 2.7 percent compared with 8.2 percent for all females in the United States. Visits were correlated with income and education. For example, those with family income less than \$4,000, and family heads with education less than 9 years, have substantially fewer visits to obstetricians or gynecologists (table 16).

Visits to ophthalmologists, otolaryngologists, dermatologists, orthopedists, podiatrists, and psychiatrists show analogous residence differentials to each other (table 17-22). The fraction of the population with visits to one of these specialists is twice as high in SMSA's as for farmers outside SMSA's.
